Abstract

Red palm weevil (*RPW*) *Rhynchophorus ferrugineus* was described as pest from tropical Asia, Mediterranean Europe, North Africa and America (California USA, 2009 and Curacao and Aruba, 2011). There is a risk for RPW invasion in South and Central America, where the weevil could infest economic palms as coconut and Guinean oil palm. The possible invasion represents a severe risk to Brazilian agriculture, and now RPW is an A1 quarantine pest with pending alert. Having available a preventive strategy of monitoring and control before the pest enters the country would mitigate the threat for the agriculture. Because of this we are developing in Brazil a semiochemical and biological control based strategies for RPW early detection and control. We set tests with Ferrugineol in olfactometer and lured traps in field to evaluate that semiochemical use to evaluate luring of the South American palm weevil (*SAPW*) *Rynchoporus palmarum* as a model pest. Moreover, biological control agents such as entomopathogenic fungi and nematodes are now available for virulence bioassays in Brazil. Field tests will be conducted with a combination of semiochemical and biological agents to determine the level of control with *R. palmarum*. Subsequently, tests with RPW outside Brazil will be carried out. We expect to find promising combination of mass trapping and biocontrol agent to propose an effective action for the RPW management and the contemporary evaluation of its control efficacy. The study will suggest a new component to develop sustainable control strategies by the joining of intercontinental experiences and approaches.

Keywords: Palmaceae, pest alert, insect attack, microbial control, ethological control, America.

Introduction

Red palm weevil, *Rhynchophorus ferrugineus* (Olivier, 1970) (Coleoptera: Curculionidae), hereafter RPW, is endemic in large areas of Asia, but has invaded the Middle East and Europe in the 1980’s, and more recently North America and the Caribbean. The adult beetles are relatively large, ranging from two to four centimeters long, and usually exhibit a rusty red color. However, many color variants exist, which often lead to mis-identifications (Rugman-Jones et al. 2013). The larvae excavate galleries up to a meter long and propagate microorganisms (Scrascia, et al., 2016) in the stipe of a palm trees, thereby weakening and eventually killing the host plant. As a result, the weevil is considered a major pest in palm plantations in the world, including the coconut palm, date palm and oil palm (Rochat et al., 2017).

Since 1972 RPW was detected and initiated dispersion in tropical Asia (Indonesia). Between 1980 to 1994 its range expanded to India, the Persian Gulf, and Israel until arriving in North Africa and Mediterranean Europe (Italy, Portugal and Spain) (Rochat et al., 2017). In 2009 RPW was detected in California and in December 2008 in the Caribbean island of Curacao (Roda et al., 2011) and in 2009 in the Caribbean island of Aruba near the Venezuelan coast (Löhr, 2015).

The arrival of this pest to Curaçao is suspected to be due to the importation of mature date palms from Egypt for landscaping in hotel and residential developments (Roda et al., 2011). Shipments of palms from Curacao to Aruba, and the lack of local phytosanitary policies and regulations, have resulted in the most recent establishment of RPW on Aruba. Fiaboe and Roda, (2012) presented prediction maps, based on the adaptability characteristics of the pest, with pest establishment likely in all tropical and subtropical environments of South and Central America and Central Africa.

The first sign of infestation by the pest is yellowing and wilting of palm leaves. The crown wilts first, and lower leaves will follow, due to damage to vascular tissue. Major symptoms such as crown loss or leaf wilt are usually only visible long after the palm has become infested. By the time these external symptoms are observed, the damage is usually sufficient to kill the tree, and the infestation may have been present for six months or longer. In high-density infestations, sounds of the larvae burrowing and chewing can be heard by placing one's ear to the trunk of the palm. Recent research has been conducted using electronic listening devices or dogs trained to recognize the scent of weevils or palm decay to detect infestations at low densities earlier in the process (Rochat et al., 2017).

The prevention of entry of high risk organisms to potentially vulnerable countries is necessary. Such prevention can be achieved through offshore mitigation.
strategies ranging from diagnosis of the presence/absence of a pest threat in adjacent countries and/or territories to eradication. The principal risk at present, is the invasion of South America by RPW, in particular for the main producer countries of commercial palm species like Brazil and Colombia. Brazil has 280,000 hectares cultivated with coconut and 210,000 hectares with oil palms (ABRAPALMA, 2017), while Colombia has 30,000 hectares cultivated with coconut and 470,000 hectares with oil palms (Dane, 2015.; Abrapalma, 2017) which would be endangered by the eventual invasion of R. ferrugineus.

In America, another palm weevil exist, with similar behavior and biology, and can be a model for RPW management, called South American palm weevil SPW, Rhynchophorus palmarum (Coleoptera: Curculionidae). This weevil is common in virgin forests and in agroecosystems infesting all commercially important palm species mainly of Cocos nucifera L. (Arecales: Areaceae), Elaeis guineensis Jaq. (Arecales: Arecaceae) (Sánchez and Cerda, 1993), in addition to ornamental palm species. The larvae of R. palmarum feed exclusively on live vegetative tissue. Studies on the population dynamics of this species in Brazil showed that the maximum adult population peaks during the dry season (Schuiling and Van Dinther, 1981). Bain and Fedon (1951) determined that R. palmarum is the most important vector of the phytonematode Bursaphelenchus cocophilus (Cobb) (Aphelenchida: Parasitaphelenchidae) which is the causal agent red ring disease of coconut and oil palm disease. The nematode is an obligate parasite distributed in all tissues of the plant. Red-ring disease has reached epiphytotic levels in the past (Griffith, 1968). The external symptoms on infested palms are a progressive yellowing of the foliar area, destruction of the emerging leaf and flowers necrosis. Leaves start to dry in ascending order in the crown; the apical leaf bends and eventually drops. However, these external symptoms are not sufficient for clear diagnosis. Internally, the galleries and damage to leaf-stems produced by the larvae are easily detected in heavily infested plants. Large economic impact of SPW in South and Central America has been reported in Brazil, Colombia, Venezuela and Costa Rica. The larvae of SPW feed on the tender tissue in the crown of the palm, often destroying the apical growth area and eventually causing death of the palm. Economic damage depends on the palm species and on the number of infesting larvae (Dalbon et al., 2018).

Esser and Meredith (1987) estimated that several million USD are lost annually due to the association of red-ring disease and SPW. They estimated that 800 ha of coconut plantations were abandoned due to this disease in Grenada, with 22% of the coconut palms were infested with red-ring disease. A similar situation seems to be common in other countries in America. More recently in Colombia, in the years 2014-2016, the damage of SPW in the pacific coast affected 8,000 hectares of coconut palms and 470,000 ha of oil palm. In Brazil R. palmarum affected coconut and oil palms an area of at least 250,000 hectares.

Control strategies have to take into account that SPW is a pest in its own right and a vector of B. cocophilus. The control of red-ring disease is currently conducted by controlling the insect vector but there is no efficient control method of the nematode. Chemical control of the insect, although often attempted, is not successful (Hagley, 1963). Cultural control consisting in the eradication and burning of affected trees reduce infestation. Chemical killing and drying of infected plants also reduce infestation (Griffith, 1987), as larvae need living plant tissue in order to survive. The most widely used control methods are based on the capture of adults with traps baited with rotting plant materials, such as palm tissue, pineapple and sugar cane. Recent traps, use synthetic pheromone based to capture the insects. Moura et al. (1989) and Rochat et al. (1991a) showed that males produce an aggregation pheromone while feeding, attracting males and females equally. Rochat et al. (1991b) identified the pheromone as 2(E)-6-methyl-2-hepten-4-ol, naming it rynchophorol.

SPW was added in 2005 to the EPPO A1 action list, and endangered EPPO member countries are thus requested to regulate it as a quarantine pest. Rhynchophorus palmarum presents a significant phytosanitary risk to date palms in Central America, North Africa, and to ornamental palms planted throughout the Mediterranean basin. At present, an integrated pest management (IPM) system for SPW in South America does not exist. New tools, including biological control and further ecological control methods are under development at Universidade Federal of Alagoas in Brazil and Embrapa Tabuleiros Costeiros.

Potential strategies of early detection and control of red palm weevil in Brazil

The potential control tools for R. ferrugineus before its arrival in South America must lie on a preventive and protective approach (Porcelli and Cornara, 2013 and Porcelli et al., 2012), given the previous failure experienced in purely mass-trapping based control.

In the specific case of R. ferrugineus, the rapid detection and availability of an array of control tools would avoid great economic losses for the permanent crops of coconut and oil palm. To develop biological and ethological control strategies for the control of palm weevils (Rhynchophorus palmarum and R. ferrugineus) is necessary to evaluate native and exotic biological agents and semiochemicals, to determine control efficacy, initially in SPW like pest control, to determine the more effective biocontrol for the future containment of RPW in Brazil and South America (Dalbon et al., 2018).

Exploitable foreground

Some examples of biological agents for evaluation, selection and use in IPM for R. palmarum and potentially R. ferrugineus, in case of invasion in South America, will be mentioned in this paper.

Microbial Agents: Pathogens like fungi (Beauveria spp., Metarhizium spp.) and nematodes (Steinerema spp., Heterorhabditis spp.) have been applied to suppress pest populations of SAPW and RPW. A wide range of microorganisms suppress pests by producing toxins, causing disease, preventing establishment of other microorganisms
or possibly by other mechanisms. Such microorganisms include bacteria, viruses, fungi and nematodes.

Entomopathogenic fungi, have been applied in Brazil since the 1990s. *Beauveria bassiana* strains have been isolated from dead weevils (Santana and Lima, 1992). Since then, EMBRAPA has conducted laboratory and field bioassays in order to develop the pathogenic *B. bassiana* strain CPATC 032 as an effective biological control of *R. palmarum*. The inoculation of adults in pheromone traps (capture – release) can be used to disseminate fungal conidia to other individuals due to the aggregation behavior. Additionally, fungal suspensions can be sprayed on plants (Ferreira and Lima, 1996). Inoculation of fungal conidia of CPATC 032 in combinations with pheromone traps have resulted in reduction of insect population level up to 72.2% (Ferreira and Lima, 1996).

Entomopathogenic nematodes (Rhabditida: Steinernematidae and Heterorhabditidae) have been described as an additional biological agent for control of adults of SAPW. The main research had started in 2014 through cooperation between Embrapa Tabuleiros Costeiros and Federal University of Alagoas. Actually in Embrapa in alliance with Colombian Corporation of Agricultural Research Center (AGROSAVIA) created a complete entomopathogenic nematodes bank with species and native strains like *Heterorhabditis amazonensis* JPM4; *Steinernema carpocapsae* Santa Rosa strain; *Heterorhabditis* sp. P5; *Steinernema feltiae*; *Steinernema brasilienise*; *Heterorhabditis amazonensis* RS03. *Heterorhabditis amazonensis* RS05., *Heterorhabditis bacteriophora*, *Heterorhabditis amazonensis* MSC01. (Acevedo et al., 2018). For RPW, *Heterorhabditis bacteriophora* and *Steinernema carpocapsae* applied in field conditions with chitosan formulation, cause over 80% mortality. Laboratory tests in Brazil indicated that nematode-induced mortality was significantly greater than that produced by the following native nematodes: *S. carpocapsae* Santa Rosa strain, *H. amazonensis* strain JPM4, *S. brasilienise*, *Heterorhabditis* sp P5, with mortalities in larvae and adults between 80 to 100%. The preliminary results suggested that the use of selected EPN species in field experiments are needed to evaluate their potential under environmental conditions for the control of SAPW and EPN and could use in RPW trials as a potential biological control agent (Acevedo et al., 2018).

### Tachinid parasitoids

The natural occurrence of the tachinid parasitoids *Billaea rhynchophorae* and *Billaea menezesi* on larvae of the palm weevil *Rhynchophorus palmarum* (L.) has been documented in plantations of piassava palm (*Attalea funifera* Mart.) and African oil palm (*Elaeis guineensis* Jacquin), in Ilheus, southeastern Bahia, Brazil (Moura et al., 1993, 2006). The average parasitism ranged from 40% up to 72%. The bi ecology of these parasitoids is currently subject of research by a consortium led by AGROSAVIA with contributions of CEPLAC and EMBRAPA with the aim to introduce the parasitoids to Colombia. The potential of these parasitoids has been completely overlooked in attempts to control *R. ferrugineus* in the Mediterranean and the Gulf region.

An artificial method of massive production of this parasitoid is still unavailable. The development of a method of mass production for an inundative liberation would be an additional management practice for *R. palmarum* and *R. ferrugineus* IPM. Mass rearing of tachinid parasitoids on artificial diet has been developed for other tachinid species (Dindo et al., 2006; 2007) and an effort will be made to adapt this technology to *Billaea* spp.

### Pest behavior-modifying chemicals

Semiochemicals are important tools for pest management, either for luring pests to traps, or for disrupting mate or host location. Pheromone-based trapping systems have been used as an efficient method in RPW IPM. Early detection and monitoring help to plan further actions, whereas mass trapping reduces population and infestation levels. Hallett et al. (1999) reported that males of RPW were found to produce the aggregation pheromone 4-methyl-5-nonanol (ferrugineol), which attracts both males and females. The use of pheromone-based trapping and an effective management of RPW have been widely demonstrated in the Middle East (Hallett et al., 1999; Soroker et al., 2005; Faleiro et al., 2011). The best semiochemical-based trapping system for RPW in Mediterranean basin is composed of three main components: trap, ferrugineol (the aggregation pheromone) and natural compounds emitted by the host plant (kairomone).

The synthetic kairomone (ethyl acetate/ethanol) was reported to improve the attractant level of ferrugineol. The synthetic blend was as effective as the natural kairomones as co-attractants (plant material + molasses) (Vacas et al., 2017). Though *R. ferrugineus* and *R. palmarum* are closely related, they do not share the same host plant range. The analysis of volatiles from hosts and non-host plants (green leaves, male inflorescence, healthy meristem and decaying tissues) may allow the identification of new kairomones or repellents and masking odours.

The biological control by using entomopathogenic microorganisms is another important technique to be included in any IPM program. The fungi *Beauveria bassiana* and *Metharizium anisopliae* causing high *R. ferrugineus* mortality rates, ranging from 60 to 87%, have been described (Gindin et al., 2006.; Dembilio et al., 2010; Lo Verde et al., 2015). Semiochemical-based control methods including mass trapping and attract and infect procedures using entomopathogenic fungi to control RPW have also been reported. Laboratory and field trials have shown that these strains have enormous potential for controlling this palm pest.

### Perspectives for integrated pest management for all strategies of control against *R. palmarum* and *R. ferrugineus* in the field in Brazil

The major components of the IPM strategy for *R. ferrugineus* and *R. palmarum* are surveillance, trapping the weevil using pheromones lures, detecting infestation by examination of palms, implementing quarantine measures, training and education (Abraham et al., 1998). In Saudi Arabia, Vidyasagar et al. (2000) successfully developed an IPM...
programme which, in addition to mass pheromone trapping, included a survey of all cultivated gardens and systematic checking of all palms for infestation. A more detailed review of control strategies and IPM for the weevil were also published (Ramachandran, 1998; Murphy and Brisco, 1999; Faleiro et al., 2011).

The entry of RPW in Brazil without a preventive strategy of monitoring, control and integrated management would be a critical threat for agriculture. In order to develop local early detection and control of RPW in Brazil, we have developed a semiochemical-based and biological control strategy. We set Ferrugineol-lured traps to try attraction tests targeting the South American Palm Weevil (SAPW) Rhynchophorus palmarum (Coleoptera Curculionidae) as a model pest. Moreover, kairomones from C. nucifera and E. guineensis. Ferrugineol in combination with biological control agents in further studies of chemical ecology will contribute to RPW control. Field tests will be conducted by a combination of semiochemical and biological agents to determine the level of control obtained with R. palmarum. Subsequently, tests with RPM outside Brazil will be carried out. As a result, we expect to evaluate ferrugineol and other effective volatile compounds for monitoring R. ferrugineus after the occurrence of the pest (early detection) in Brazil and contribute with others strategies in IPM of this pest. We expect to join efforts with different institutions in Brazil, South America and International Research Centers and Universities to contribute towards improved RPW management.
